

SPINAL BONE IMPLANT

BACKGROUND OF THE INVENTION

The present invention relates to implantable spinal devices and methods for their use. More particularly, the present invention relates to interbody devices formed of bone that may be utilized in spinal fusions.

A variety of interbody implants are available for spinal fusion procedures. These implants have been manufactured of various materials including steel, titanium, composites, allograft, xenograft or other biocompatible materials, and have the necessary strength to prevent the disc space from collapsing before fusion has occurred. Other techniques for spinal fusion include the placement of bone graft material in the disc space along with a plate or rod construct that spans the affected disc space. One disadvantage to the above devices is that once fusion has occurred, the implants and hardware used to maintain the stability of the segment is unnecessary and remains in the body as a foreign object.

Other types of implants have been developed from bio-compatible metals which incorporate threads on the outer surface of the implant that retain the implant in the disc space after it is threaded therein. Still other implants have been developed that are made from bone. Examples of such spacers made from bone having use in spinal procedures are disclosed in U.S. Patent No. 5,989,289. The spacers in the '289 patent are provided with vertebral engaging surfaces on the upper and lower faces of the implant to resist migration of the implant in the disc space and/or expulsion of the implant from the disc space. While spacers made of bone offer

much improved incorporation in fusion procedures, the inherent brittle nature of bone resulting from a high mineral content, particularly load-bearing cortical bone, severely limits its potential for use in applications that require the implant to resist loading other than bearing or compression type loading. For example, cortical bone typically consists of approximately 70% mineral content and 30% non-mineral matter. Of this non-mineral matter, approximately 95% is type I collagen, with the balance being cellular matter and non-collagenous proteins.

Bone grafts have commonly been used in a fixed shape, pulverized, or as pliable demineralized bone. One form of a pliable bone graft is a demineralized bone material typically in the form of a sponge or putty having very little structural integrity. While a demineralized bone segment may retain properties suitable to support bone ingrowth, the structural properties of the bone are altered by removal of its mineral content. Thus, such bone sponges and putties may not typically be used in load-bearing applications.

Therefore, there remains a need for bone implants having the requisite load carrying capabilities for applications that require both bearing or compression load carrying capabilities along with capabilities for resisting loading other than bearing or compression type loading.

SUMMARY OF THE INVENTION

The present invention is directed to a bone implant having a rigid portion for insertion between adjacent bony structures and a flexible portion for securement to the adjacent bony structures.

According to one aspect of the invention, there is provided an implant that has a body portion positionable in the disc space between adjacent upper and lower vertebrae. The implant further includes an upper member and a lower member extending from the body portion along the upper vertebral body and the lower vertebral body, respectively. The body portion, the upper member, and the lower member are each made from bone material.

According to another aspect of the invention, there is provided an implant that includes a bone body with a first bearing surface and a second bearing surface. An upper bone member extends from the body in a first direction and a lower bone member extends from the body in a second direction opposite the first direction. The upper and lower bone members are at least partially demineralized and flexible.

According to a further aspect of the invention, there is provided a spinal fusion implant that is adapted for insertion into the space between adjacent first and second vertebral bodies. The implant includes a bone body having a first bearing surface for contacting an endplate of the first vertebral body and a second bearing surface for contacting the endplate of the second vertebral body. At least one flexible portion extends from the bone body so that it can be secured to one of the first or second vertebral bodies outside the disc space.

According to yet another aspect of the invention, there is provided a method of preparing a bone implant. The method includes providing a rigid bone segment having a body portion with an upper bearing surface and opposite lower bearing surface. The rigid bone segment further includes an upper flange member and an opposite lower flange member that each extend from the body portion. The upper and lower flange members are at least partially demineralized so as to be flexible.

According to another aspect of the invention, there is provided a method of inserting an interbody fusion implant made of bone. The method includes: providing an implant formed of bone and having a body portion with an upper bearing surface and opposite lower bearing surface, the rigid bone segment including a flexible upper flange member and an opposite flexible lower flange member each extending from the body portion; accessing the disc space between adjacent vertebrae; inserting the body portion of the implant into the disc space; securing the flexible upper flange member to the upper vertebra; and securing the flexible lower flange member to the lower vertebra.

According to a further aspect of the invention, a method of preparing a bone implant, is provided. The method includes obtaining a rigid bone segment and forming from the rigid bone segment an implant having a body portion with an upper bearing surface and opposite lower bearing surface, the rigid bone segment further including an upper flange member and an opposite lower flange member each extending from the body portion.

These and other aspects, advantages, features, embodiments, and objects of the present invention will be apparent to those skilled in the art based on the following descriptions of the illustrated embodiments of the present invention.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 is perspective view of an implant according to the present invention.

FIG. 2 is a side elevational view of the implant of FIG. 1 inserted in the disc space between adjacent vertebrae.

FIG. 3 is a side elevational view of another embodiment implant according to the present invention.

FIG. 4 is a perspective view of yet another embodiment implant according to the present invention.

DESCRIPTION OF THE ILLUSTRATED EMBODIMENTS

For the purposes of promoting an understanding of the principles of the invention, reference will now be made to the embodiments illustrated in the drawings and specific language will be used to describe the same. It will nevertheless be understood that no limitation of the scope of the invention is thereby intended. Any such alterations and further modifications in the illustrated devices, and such further applications of the principles of the invention as illustrated therein are contemplated as would normally occur to one skilled in the art to which the invention relates.

Referring now to FIG. 1, there is shown an implant according to one embodiment of the present invention. Although implants according to the present invention may have many uses, the embodiment shown in FIG. 1 is particularly adapted for promoting interbody fusion in the spine. Specifically, FIG. 1 illustrates a bone implant 10 having a first substantially rigid body portion 12 that extends between a leading end 30 and a trailing end 32. Implant 10 further includes at trailing end 32 a first or upper flange member 14 that extends upwardly from body portion 12 and a second or lower flange member 16 that extends downwardly from body portion 12. Preferably, body portion 12 and flange members 14, 16 are made from a single piece of bone material, and the flange members are integral with body portion 12. However, other embodiments contemplate that the flanges are made from a separate piece of material, such as bone or cartilage, and secured to body portion 12 via fasteners or other known bonding technique.

Flange members 14 and 16 have been at least partially demineralized to create flexible flange members extending from rigid body portion 12. The demineralized portion of implant 10 can extend through rigid body portion 12 between upper flange member 14 and lower flange member 16 as illustrated. Alternatively the demineralized portion can extend partially into rigid body portion 12, or terminate at the junction between flange members 14, 16 and rigid body portion 12. Preferably, at least flange members 14 and 16 have been completely demineralized to provide maximum flexibility. The flexibility created by demineralization permits flange members 14 and 16 to be movable with respect to rigid body portion 12 and with respect to each other, and thus function similarly to a ligament extending between and secured to the adjacent bony structure and to body portion 12.

Body portion 12 of implant 10 has a cavity 18 which is preferably derived from the intermedullary canal of the bone from which implant 10 is obtained by a cross-cut across the diaphysis of a fibula, femur or like long bone. Cavity 18 provides an area to receive material that promotes bony incorporation and fusion. Prior to positioning body portion 12 into the disc space, bone growth promoting material 28 may be positioned in cavity 18 to encourage bone growth into and through body portion 12. Bone growth material can be any type of material known in the art. As shown further in FIG. 2, upper flange member 14 includes a first fastener bore 20 for receiving a first fastener 24 and lower flange member 16 has a second fastener bore 22 for receiving a second fastener 26. The fasteners of the present invention can be in the form of a threaded screw and made from metal, bone, polymer, bio-absorbable material, or other material known in the art.

As shown in FIG. 2, one specific application of the present invention implant 10 contemplates use for fusion of the vertebrae of the cervical spine. In this embodiment implant 10 is obtained from the fibula. Body portion 12 can have any shape, including a specific shape for use in the cervical region, such as those shapes identified in U.S. Patent No. 5,989,289 which is incorporated herein by reference in its entirety. The vertebrae V1 and V2 are accessed from an anterior approach using known surgical techniques. The disc material is removed and the disc space height is restored, if necessary, using known surgical techniques. Implant 10 is inserted into the prepared disc space. Rigid body portion 12 is adapted to provide structural support between the respective lower endplate of upper vertebra V1 and the upper endplate of vertebra V2. In the illustrated embodiment, rigid body portion 12 has a height H sufficient to provide support for and maintain the desired spacing between adjacent vertebra V1 and V2. Fusion between vertebrae V1 and V2 is obtained with bone growth through cavity 18, which is filled with bone growth material 28. Fusion between the vertebrae can be further promoted by reducing the endplates to bleeding bone prior to insertion of implant 10.

Implant 10 has upper bearing surface 25 that contacts and supports upper vertebral body V1 and lower bearing surface 27 that contacts and supports implant 10 on lower vertebral body V2. Body portion 12 has height H between upper bearing surface 25 and lower bearing surface 27 that is substantially equal to the height of disc space formed between vertebra V1 and vertebra V2. It will be understood by those skilled in the art that in the preferred embodiment illustrated herein, the height H is substantially constant. Furthermore, while a uniform height implant is shown in FIG. 2, it will be understood that the implants of the present invention may have a

tapered height such that the implant could be utilized for establishing or maintaining the proper curvature in the spine. Rigid body portion 12 has sufficient rigidity and structural integrity to substantially maintain height H and to withstand normal forces applied to the spinal column. Flange members 14 and 16 need not have such structural requirements, although, preferably, each assists in the implant stability by maintaining rigid body portion 12 in the disc space between the two vertebrae.

Fasteners 24 and 26 are placed through the corresponding fastener bores 20 and 22 in the upper and lower flange members 14 and 16, respectively, to stabilize implant 10 in the disc space. Since flange members 14 and 16 are flexible, they can be manipulated and positioned adjacent the vertebral bodies outside the disc space without the creation of large shear and bending stresses in implant 10 at the junction between flange members 14, 16 and body portion 12.

While it is contemplated in one specific embodiment that implant 10 have application for fusion of a cervical region of the spine, application at other regions of the spine and at other joints where it is desirable to have a bone implant with a rigid body portion with a pair of flexible members extending therefrom are also contemplated. Bone implant 10 provides the desirable features of being formed of a highly successful bone fusion material, i.e. natural bone, with the advantages of having flexible members made from bone to secure the rigid bone body portion of the implant at the implantation location.

In another surgical technique, a tensile force can be applied to upper flange member 14 prior to insertion of fastener 24. When fastener 24 is secured to vertebra V1, the tensile force is

released. Fastener 26 can be similarly inserted through bore 22 of a tensioned lower flange member 16. The pre-tensioned upper flange member 14 and pre-tensioned lower flange member 16 thus apply a compressive load on body portion 12 in the disc space, further promoting fusion and incorporation of implant 10 and inhibiting expulsion of implant 10 from the disc space.

Referring now to FIG. 3, a further embodiment implant is shown and designated as 50. Implant 50 is substantially identical to implant 10. Implant 50 includes rigid body portion 52 with flexible upper flange member 54 and flexible lower flange member 56 extending therefrom. A first fastener bore 60 is formed through upper flange member 54 and a second fastener bore 62 is formed through lower flange member 56. Body portion 52 includes a cavity 58 in which bone growth material 64 is placed.

Body portion 52 further includes a number of upper bone engagement ridges 68 formed on and extending upwardly from upper bearing surface 66 with an identical set of lower ridges 72 formed on and extending downwardly from lower bearing surface 70. It will be understood that while ridges have been shown in the illustrated embodiment, it is contemplated that there are a variety of structures, which could provide a surface for effective engagement with the vertebral bodies to limit expulsion from the disc space. Examples of some such further structures are discussed in U.S. Patent No. 5,989,289. Further, the endplates or bearing surfaces of the adjacent bony structure can be roughened or otherwise shaped to retain the body portion 52 in its inserted position.

Referring now to FIG. 4, there is shown another embodiment implant 80 for use in vertebral fusion procedures that has particular application in a posterior approach to the disc

space, although implant 80 may be used in other approaches, including anterior and lateral approaches. Implant 80 has a rigid body portion 82 with an upper flange member 84 and a lower flange member 86 each extending from rigid body portion 82 at its trailing end. Implant 80 does not have a cavity and can therefore have a width that is less than the width of implants 10 and 50. Access to the disc space between adjacent vertebra is achieved as known in the art. Examples of such techniques and posterior bone implants are discussed in PCT Publication No. WO 00/24327, which is incorporated herein by reference in its entirety. Once access is achieved, the disc space is distracted if necessary. Implant 80 is moved into the disc space with body portion 82 positioned between the adjacent vertebrae and upper flange member 84 and lower flange member 86 positioned adjacent the vertebral bodies outside the disc space. Once body portion 82 is secured in the disc space D, fasteners can be used to secure the flange members to the respective adjacent vertebral body. It will be understood that a second implant can be placed in the disc space adjacent the first inserted implant to provide further stability.

Although not illustrated, the implants of the present invention can have a slot or threaded bore for engaging a driving tool adapted to position and push the implant into the disc space.

The bone for the implants of present invention is preferably selected from one of the femur, tibia, fibula radius, or ulna or other bone segment having the requisite cortical bone strength. It is further contemplated that implant 10 can be autograft, allograft, or xenograft bone with the bone being treated as known in the art for subsequent implantation into the recipient. Specifically, the bone implant may be selected from donor bone having sufficient resistance to

compression between the upper and lower surfaces to find application in the intended environment.

Creation of the demineralized portion of the bone will now be described. The processing involves the use of donor bone with processing in a clean room environment within a bone processing facility. Such donor bone may include allograft from human sources or xenograft from animal sources. Further, it is contemplated that as technology advances in the area of bone processing, the donor bone may be generated in the manufacturing process, either by bone growth or by a processing of constituent components of bone to create artificial materials having properties very similar to bone. More specifically, while any available allogenic or xenogenic bone stock may be utilized for the procedure, cortical bone is conventionally preferred for spinal fusion for its structural properties, although cortical cancellous or cancellous bone may be used depending upon the particular requirements for the implant.

In further processing, the connective tissues are removed and the bone is cleaned, rinsed, and defatted using a solvent such as ethanol or hydrogen peroxide. The bone is then machined or otherwise shaped using conventional techniques to create its final shape. The upper and lower flange members and, if required, the body portion are demineralized to create the required flexible capability. Penetration of the demineralization fluid into the bone adjacent the desired area of flexibility may be controlled by hydrostatic pressure thereby limiting the area of demineralization. The amount of mineral removed from the bone may be adjusted to create the desired amount of flexibility. This demineralization conventionally uses an organic acid such as hydrochloric, nitric, or citric acid. Preferably, the demineralization solution comprises 0.1 to 1.0

N HCl, most preferably 0.3 N HCl. If a **xenograft** is used, known techniques on the utilization of organic solvents to inactivate bone proteins and reduce antigenicity may be applied at this point. Additionally, the use of glutaraldehyde may take place in order to further cross-line the collagen structure following removal of the mineral portion. Once the implant has been machined and partially demineralized, it may be stored prior to insertion.

Although the above-described processing is disclosed herein as a preferred embodiment, it is contemplated that other suitable processes may be used.

While the invention has been illustrated and described in detail in the drawings and foregoing description, the same is to be considered as illustrative and not restrictive in character, it being understood that only the preferred embodiments have been shown and described and that all changes and modifications that come within the spirit of the invention are desired to be protected.
